

OPEN ACCESS ATLAS OF OTOLARYNGOLOGY, HEAD & NECK OPERATIVE SURGERY

INCUS- & MALLEOSTAPEDOTOMY

Tashneem Harris & Thomas Linder

Stapedotomy refers to the calibrated fenestration of a fixed footplate and insertion of a prosthesis. *Prof Ugo Fisch* first introduced the terms *incus-stapedotomy* where the prosthesis is attached to the long process of the incus, vs. *malleostapedotomy* where the prosthesis is attached to the malleus handle.¹ The surgical steps of both procedures will be described as per *Prof Ugo Fisch*.

Otosclerosis is the most common indication for stapedotomy. Histology of temporal bone specimens show that there may be a fairly high incidence (up to 30%) of *additional malleal fixation* in otosclerosis.² Hyalinisation and ossification of the anterior malleal ligament are related to the duration of otosclerosis.² Fixation of the malleus head and incus body is usually found in narrow external ear canals. The reported incidence of malleal fixation in clinical studies varies significantly for both primary (0.6 - 6%)^{3,4} and revision surgery (3-37%).^{5,6} In a study (unpublished data) conducted by the senior author (T.L), the incidence was found to be 5% with primary surgery.

The best way to *assess mobility* of the ossicles and the anterior malleal ligament is by visual assessment of the mobility of the ossicles on direct palpation. This requires adequate surgical exposure; it is difficult to assess it via a limited transcanal approach. Partial fixation may be overlooked when using a limited approach.

It is the practice of the senior author (T.L) to routinely use the *endaural approach* and to systematically *expose the anterior malleal ligament* as this allows for proper assessment and identification of impaired ossicular mobility at the time of the *primary surgery*. If there is even partial fixity of the malleus or incus at primary

surgery, then a malleostapedotomy is performed. The rationale behind the endaural approach with an enlarged tympanomeatal flap and partial anterosuperior canalplasty as described by *Fisch* is primarily to improve surgical exposure to properly assess ossicular mobility⁷.

Indication for surgery

Patients with otosclerosis and a conductive hearing loss with an air-bone gap (ABG) of >20dB are candidates for surgery.

Goals of surgery

The aim of surgery is to achieve maximum hearing gain with minimal damage to the membranous labyrinth; it may be considered in 3 different categories depending on cochlear reserve of the patient:

- To achieve normal hearing in patients with normal cochlear reserve (<10dB postoperative air-bone gap)
- To achieve serviceable hearing in patients with minimal reduction in cochlear reserve and possibly to eliminate the need for a hearing aid
- To improve hearing aid satisfaction

Note that patients with advanced otosclerosis and poor cochlear reserve who no longer benefit from amplification are candidates for cochlear implantation.

Preoperative evaluation

Otomicroscopy: A normal stable tympanic membrane without retraction pockets must be confirmed with otomicroscopy.

Tuning fork tests: Tuning fork tests are a simple means to confirm conductive hearing loss and can help confirm the validity of the audiogram. They only assess a sing-

le frequency (commonly 440Hz) at a time and should be done by the surgeon.

Audiological evaluation

- Audiometric testing should be recent (≤ 3 months)
- Enables the surgeon to decide which ear requires surgery ⁸
- Includes pure tone audiometry which typically indicates conductive hearing loss involving the lower frequencies with a Carhart notch at 2kHz
- The size of the ABG provides an indication of the gain that may be achieved by surgery ⁷
- A typical audiogram for otosclerosis has a larger ABG in the low frequencies and good sound transmission at high frequencies (4kHz). A consistent pancochlear ABG is not typical for otosclerosis!
- A Carhart notch is characterised by the apparent elevation of bone conduction threshold of 15dB at 2kHz and is the hallmark audiologic sign of otosclerosis
- One can accurately determine the degree of secondary cochlear loss by making allowance for the Carhart notch when interpreting bone conduction thresholds; if the bone conduction threshold is greater than 15dB at 2kHz it suggests underlying cochlear otosclerosis. This can help the clinician with preoperative counselling about the anticipated outcome of surgery
- In the absence of a Carhart notch it is important to exclude other causes of conductive hearing loss which may mimic otosclerosis
- *Speech discrimination* is especially useful to determine the presence of cochlear otosclerosis when the ABG is >15 dB at 2kHz)

Tympanometry: Type A curve

Stapedial reflexes: Absent in otosclerosis

High Resolution CT (HRCT)

It is important to emphasize at this point that ***otosclerosis is a clinical diagnosis*** made on history, audiometric findings and confirmed at surgery. However, the role of *HRCT* in preoperative planning and patient counselling cannot be underplayed.

HRCT (0,5mm) is useful (but not mandatory) because it can help to confirm the presence of otosclerosis ⁹; it may identify other middle ear disorders which may mimic otosclerosis or be coexistent; it may confirm cochlear involvement by the otosclerotic focus; it is useful to assess post-operative failures and complications *e.g.* sensorineural hearing loss (SNHL) or disabling vertigo and may identify problems which need to be managed promptly *e.g.* too long a prosthesis. ¹⁰

The absence of a Carhart notch suggests another cause for a conductive hearing loss. There have also been numerous case reports and series of ***superior semicircular canal dehiscence*** and other pathology which may mimic otosclerosis and are unmasked by stapedotomy (stapedial reflex is present in cases of dehiscence only) ^{11,12,13,14}

It is the practice of the senior author (T.L.) to do a HRCT scan (0,5mm-1mm) whenever patients have the following features on pure tone audiogram:

- Conductive hearing loss but absent Carhart notch
- Equal ABG across all frequencies
- Mixed hearing loss
- All cases of revision stapes surgery

The following pathologies can be excluded with preoperative HRCT scan:

- Conductive hearing loss with an absent stapedial reflex:
 - Fixation of head of malleus to lateral tympanic wall
 - Fixation or erosion of incus
 - Congenital ossicular deformity
 - Round window atresia
 - Tympanosclerosis causing obliteration of footplate
- Conductive hearing loss with an intact stapedial reflex:
 - A 3rd window: superior or posterior semicircular canal dehiscence
 - Tympanic facial nerve neuroma blocking the stapes
 - Gusher syndrome: enlarged internal auditory meatus, enlarged endolymphatic aqueduct
 - Anomalous facial nerve

CT scan checklist prior to performing stapedotomy

- Can you see an otosclerotic focus (*fissula ante fenestrum*)?
- Is there obliteration of the oval and round windows?
- Is there cochlear otosclerosis? (It is possible to have fairly extensive cochlear otosclerosis with minimally reduced hearing loss)
- Is there a risk of a CSF gusher? (enlarged aqueduct, enlarged internal auditory meatus)
- Is there semicircular canal dehiscence?
- What is the position of the tympanic segment of the facial nerve?
- Are there any other ossicular abnormalities e.g. fixation of the malleus to the lateral wall of the epitympanum?
- Is there a stapedial artery?

CT checklist for revision surgery

- Is the prosthesis in the correct position or is it displaced?

- In cases of vertigo, what is the depth of insertion of the piston into the vestibule?
- Is there evidence of obliterative otosclerosis, particularly of the round window, which may have been missed at primary surgery?
- Is there superior canal dehiscence or any other 3rd window?
- Is there additional fixation of the malleus and/or incus?

Anaesthesia

- General or local anaesthesia may be used
- Performing the procedure under local anaesthesia depends on the patient and level of experience and level of comfort of the surgeon
- Antibiotics are not routinely used
- Antiemetics are administered intra-operatively

Surgical steps

Endaural approach (right ear)

- Insert a nasal speculum in the ear canal for exposure (*Figure 1*)

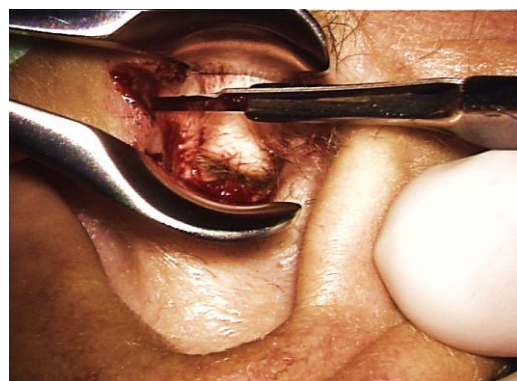

Figure 1: Nasal Speculum and helicon-tragal incision (right ear)

- Infiltrate the skin of the external ear canal anteriorly and posteriorly and the site of the endaural skin incision with

local anaesthetic (lidocaine 1% & adrenaline diluted to 1:200 000)

- Make a helicotragal incision with a #15 blade (*Figure 1*)
- It is crucial to achieve adequate haemostasis at this point to avoid subsequent troublesome bleeding
- Place two endaural retractors in the entrance of the external ear canal. The 1st retractor is placed vertically; the 2nd is placed horizontally (*Figure 2*)

Figure 2: Exposing the ear with two retractors

Meatal skin flap

- Make a *posterior incision* in the skin of the ear canal using a #11 blade, starting at the annulus at 7 o'clock (5 o'clock for left ear) and ascending upwards to end at 12 o'clock
- A 2nd incision starts anterior to the lateral process of the malleus at 3 o'clock (right ear) and passes above the tympanosquamous suture to meet the end of the endaural incision at 12 o'clock
- It is important that the tympanomeatal flap is made long enough anteriorly and that the incision stays medial to the cartilage plates
- An endaural raspator is used to separate the skin and soft tissue from the bone both anteriorly and posteriorly
- The meatal skin flap is elevated using a Fisch microraspator and an otosclerosis suction with adrenaline gauze to

separate the soft tissue from the bone as atraumatically as possible. The working end of the Fisch microraspator is held at right angles to the bone and the shoulder of the instrument pushes the adrenaline gauze strip towards the soft tissue. The suction never touches the tympanomeatal flap, but sucks on the gauze

Anterosuperior canalplasty

- The exposure may occasionally be limited by a very prominent tympanosquamous suture which requires removal with a curette or a diamond drill
- In cases where there is a very prominent anterior bony overhang which prevents adequate exposure of the anterior tympanic spine, a limited anterior canalplasty is performed using a 3mm diamond burr (*Figure 3*).

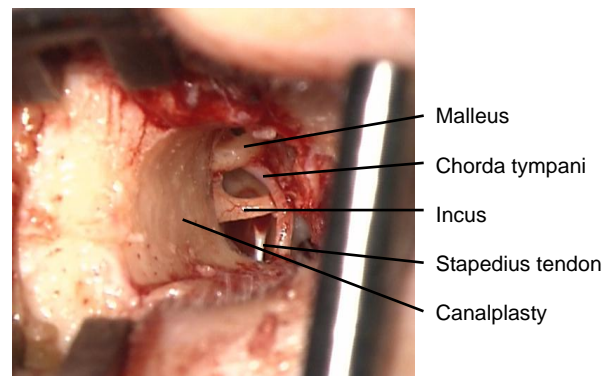

Figure 3: Anterosuperior canalplasty improves exposure

- It is very important that all bone work is done before raising the tympanic part of the tympanomeatal flap to avoid contamination of the middle ear with bone dust

Exposure of oval window

- Elevate the tympanomeatal flap towards the posterior tympanic spine in order to elevate the annulus from the sulcus

- The *pars flaccida* is elevated until the lateral process of the malleus and the anterior malleal ligament are visible
- A small curette is used to remove the posterior tympanic spine taking care to avoid damage to the underlying *chorda tympani* (Figure 4)

Figure 4: Small curette used to remove posterior tympanic spine

- Remove the rim of bone obscuring the inferior portion of the incudomalleolar joint with a curette. It is important when using the curette, to avoid subluxing the incus. The small end of the curette is used. The index finger of the non-dominant hand stabilises the curette anteriorly (Figure 5)

Figure 5: Correct handling of curette

- Always preserve *chorda tympani*. It is mobilised but kept attached to the tympanic membrane; this facilitates retraction of the chorda away from the surgical field

- The final correct exposure is obtained when the pyramidal process, the tympanic segment of the facial nerve and the inferior incudomalleolar joint are all visible (Figure 6)
- Inspecting the *round window* is important to exclude obliterative otosclerosis reaching the round window membrane and rarely, congenital round window atresia¹¹

Figure 6: Final correct exposure

Checking mobility of ossicular chain

- Check the mobility of the malleus and incus with a 1.5mm, 45° hook (Figure 7)
- Check mobility of the stapes (Figure 8)

Figure 7: Checking mobility of lateral ossicular chain

- If malleus and/or incus are fixed, then proceed to malleostapedotomy
- If the malleus and incus are mobile and the stapes is fixed then, using the 1.5mm 45° hook, elevate the malleus

handle to determine where the incudo-stapedial joint is

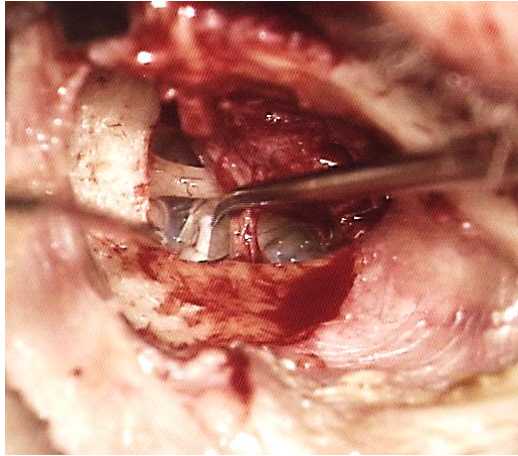

Figure 8: Checking mobility of stapes

- Use a joint knife to separate the incudo-stapedial joint
- Check mobility of the stapes again

Removal of stapes arch

- Cut the stapes tendon with fine Bellucci scissors
- Cut the posterior crus of the stapes with (left or right) crurotomy scissors
- Exposure of the pyramidal process (Figure 6) is essential to provide sufficient space for the crurotomy scissors
- Fracture the anterior crus at the level of the footplate, using a 2.5mm, 45° hook
- To fracture the anterior crus, insert the 2.5mm, 45° hook between the incus and the malleus neck, close to the footplate. The tip of the hook is close to the level of the footplate, even if the entire anterior crus is not visible
- The hook is rotated towards the promontory
- If correctly fractured, the remaining stapes superstructure has a long anterior and a short posterior crus
- Bleeding may occur from the mucosa when the superstructure is removed, in which case gelfoam with Ringer's lactate or diluted adrenaline solution is

placed over the footplate to achieve haemostasis (wait 2-3 minutes)

Determining length of prosthesis

- Accurate measurement of the length of the prosthesis is crucial
- A piston that is too long can contact or even pierce the underlying membranous labyrinth
- A piston that is too short will be displaced easily when the patient sneezes or performs a Valsalva manoeuvre
- A malleable measuring rod is used to determine the distance between the footplate and the lateral surface of the long process of the incus (Figure 9)
- Add 0,5 mm to the measured distance to account for the protrusion of the prosthesis into the vestibule

Figure 9: Measuring rod used to determine length of prosthesis

Trimming prosthesis

- The Storz titanium stapes piston is placed on a special cutting block which holds the prosthesis (Figures 10, 11)

Figure 10: Teflon-wire prosthesis

Figure 11: Cutting block

- The trimmed prosthesis is handled with watchmaker's forceps and placed upright in the 4mm hole of the cutting block while proceeding to stapedotomy
- The Storz titanium stapes piston is hygroscopic and is therefore easier to work with when wet. Therefore, the cutting block is moistened with a few drops of water before placing the piston on it

Perforating the footplate

- A set of four manual perforators are (0.3-0.6mm) are used to make the stapedotomy
- Start with the smallest perforator (0.3mm) and ensure that there is no evidence of a CSF gusher before enlarging the stapedotomy with the larger perforators (Figure 12)

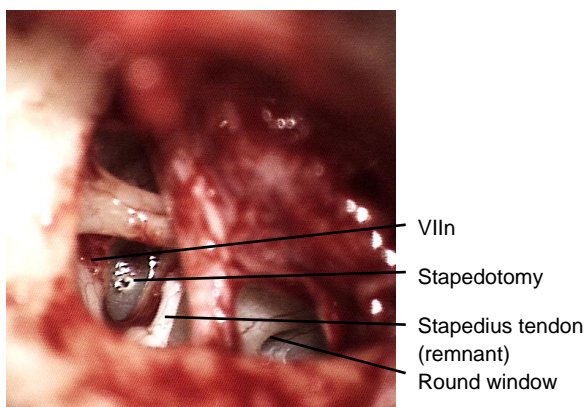

Figure 12: Initial small stapedotomy

- The safest place to make the stapedotomy opening is in the posterior two-thirds of the stapes footplate (see below)
- For a 0.4mm prosthesis the ideal diameter is a stapedotomy of 0.5mm (Figure 13)

Figure 13: Making the final 0.5mm stapedotomy

- The tip of the perforator is gently applied to the footplate without using any force at all
- The perforator is held vertically to the stapes footplate and is gently rotated between the thumb and index finger of the right hand while the left hand stabilises it (Figure 14)

Figure 14: The perforator is gently rotated between the thumb and index finger of the right hand while the left hand stabilises it

- The tip of the perforator only partially enters the vestibule as the stapedotomy opening is created by the shoulder of the perforator

Additional important points and clinical scenarios

Safest position for stapedotomy

- The risk of stapedotomy is damage to the membranous utricle and saccule which lie in close proximity to the stapes footplate
- Surgeons should know the safety margins required to perform the procedure without damaging the underlying vestibule
- The minimum distances to the utricle are at the posterior (0.58mm) and superior (0.62mm) borders of the footplate; therefore, placing a prosthesis to a depth of 0.5mm in this region of the footplate will place the utricle at risk of injury ¹⁵
- The minimum distance to the saccule is at the anterior border of the footplate (0.76 -1mm) ¹⁴
- All other measurements from the footplate to the underlying membranous utricle and saccule are >1mm
- The safest area for manipulation is therefore the ***central third in the inferior segment*** of the footplate

Choice of instrument for stapedotomy

- In the senior author's (T.L.) experience, the type of footplate is important when selecting a perforator
- An alternative to manual perforators is laser or a Skeeter drill. Lasers that have been used for stapes surgery include CO₂, KTP, Argon, Diode and Erbium: YAG lasers
- When one encounters a biscuit (thick) footplate, or a thick footplate which is

only partially fixed, then there is a risk of causing a floating footplate

- If the footplate is too thick, then it is preferable to use a drill

Footplate fracture during stapedotomy

- If only small bony fragments surround the stapedotomy opening and the opening is of the desired size, then one can carefully elevate the fragments with a 0.2mm footplate elevator to avoid the fragments from entering the vestibule and causing vertigo postoperatively (*Figure 15*)

Figure 15: Carefully elevate bony fragments with 0.2mm footplate elevator

- If the footplate has been fractured but the stapedotomy is still too small and it is not possible to enlarge the opening

without displacing the bony fragments, then the fractured segments can be removed with either a 0.2mm footplate elevator or a 0.5mm, 45° hook, such that a partial or total stapedectomy is performed. A perichondrium or fascia graft is then placed over the (partial) stapedectomy before placing the prosthesis (*Figure 16*)

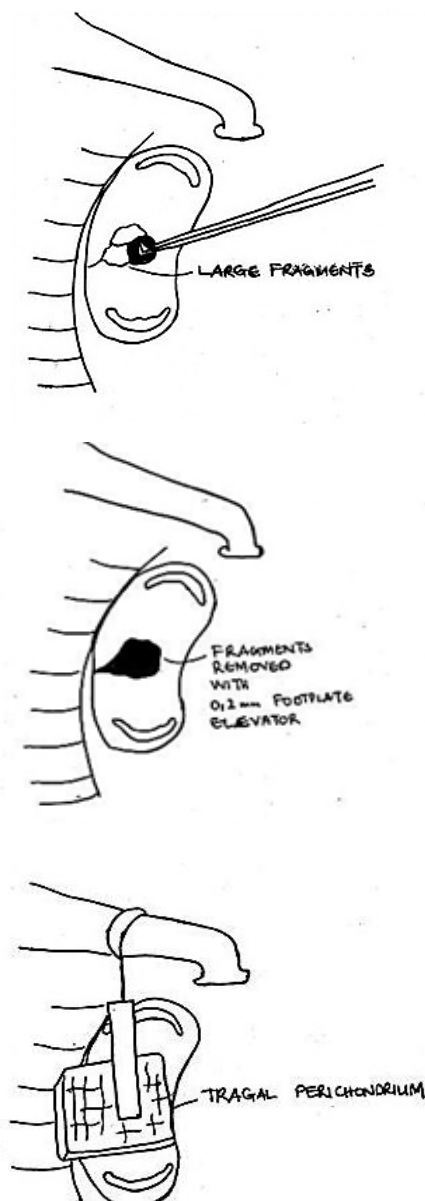

Figure 16: Partial stapedectomy sealed with a perichondrium graft before inserting prosthesis

Floating footplate

The footplate may become completely mobile before the stapedotomy has been made. Management options in this situation are:

- Proceed with the stapedotomy using a laser
- Proceed with a total stapedectomy and seal the oval window a graft (perichondrium / vein / fascia) before placing the piston prosthesis
- Postpone the surgery for one year if the stapes superstructure is still intact; the annular ligament will progressively become refixed due to otosclerosis

Inserting and crimping the prosthesis

- The prosthesis is picked up with a large crocodile forceps from its hole in the cutting block by its wire loop
- For first-time correct placement of the loop over the long process of the incus it is essential to pick up the prosthesis at the correct angle
- The prosthesis is placed onto the footplate with the wire loop over the incus
- One can estimate at this point whether the prosthesis is too long and needs to be shortened, or too short and needs to be replaced
- Using a 1mm, 45° hook, move the loop of the prosthesis along the long process of the incus to guide the shaft of the piston towards the stapedotomy opening (*Figure 17*)
- Once the piston is positioned within the stapedotomy opening, the loop of the prosthesis is crimped with a large smooth crocodile forceps to achieve a more stable coupling of the prosthesis to the incus; this is repeated with smaller smooth crocodile forceps (*Figure 18*)

Figure 17: The loop is hooked over incus with the piston resting on the footplate

Figure 18: Crimped prosthesis with piston in stapedotomy; note position of facial nerve (arrow) immediately adjacent to the prosthesis

- Using a 1.5mm 45° hook, check the mobility of the ossicular chain with the prosthesis in place
- There should be no free movement of the prosthesis on the incus when the incus is moved

Crimping technique

- To achieve good results, *correct crimping is absolutely essential*
- Loose coupling of the prosthesis to the incus will result in reduced sound transmission and inferior acoustic results¹⁶

- To crimp the loop of the prosthesis, the crocodile forceps is held with the right hand and stabilised with the left hand using the thumb and the index finger (Figure 19)
- It may be necessary to remove the horizontal soft tissue retractor to gain more space to crimp the prosthesis correctly
- Crimping is performed from the most superior part loop, so that the prosthesis loop makes even contact with the incus (Figure 20)

Figure 19: Crocodile forceps held with right hand and stabilised with left hand using thumb and index finger

Figure 20: Crimping is performed from the most superior part of the loop

- Correct angulation of the piston relative to the footplate is crucial to achieve good acoustic results. The piston must be at right angles to the footplate to avoid contact of the piston with the bony edges of the stapedotomy which

will result in attenuation of vibration and reduced sound transmission¹⁷ (Figure 21)

- Kwok, Fisch *et al* reported that crimping results depend on the instrument used for crimping and the material of the stapes prosthesis, but not on the surgeon. The straight crocodile forceps was shown in their study to produce better results than the McGee crimper¹⁷

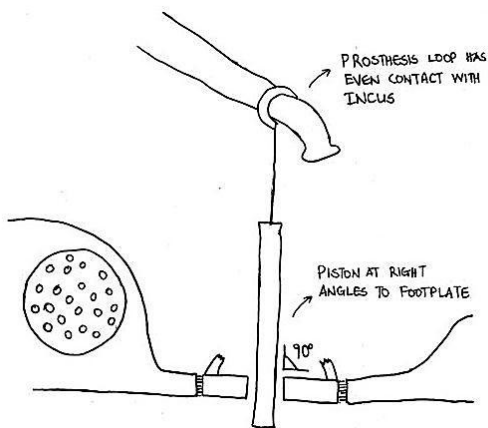

Figure 21: Prosthesis must be at right angles to footplate for optimal hearing results

Sealing stapedotomy opening

Connective tissue placed around the piston serves as a seal to prevent perilymph leakage. Once the seal has matured it also prevents displacement of the piston. The connective tissue seal also increases the sound transmitting area, so that a 4mm piston is equivalent to the surface area of a 6mm piston, thereby improving sound transmission and achieving better acoustic results. If one performs tympanometry at 2 weeks and no vertigo is induced, then the seal is adequate and it is safe for patients to fly.

- Connective tissue from the endaural incision is used to seal the stapedotomy opening
- Use a 1.5mm, 45° hook to place pieces of connective tissue around the stapedotomy

- Venous blood taken from the patient at the beginning of the procedure is stored at 3-4°C to prevent the blood from clotting until it is needed; this blood is now used to seal the stapedotomy opening

Repositioning tympanomeatal flap

- Reposition the tympanomeatal flap
- If any small tears in the tympanomeatal flap are noticed, then temporalis fascia is harvested and underlay grafting is done

Packing and wound closure

- Gelfoam pledgets are placed in the bony canal to secure the meatal part of the flap
- Do not place gelfoam pledgets over the tympanic membrane as they may swell and displace the prosthesis inwards causing vertigo
- Two pieces of Ivalon® sponge are placed in the external ear canal
- The endaural incision is closed with 4/0 nylon sutures. One subcutaneous stitch may help to readapt the wound edges
- An outer strip of gauze which has been impregnated with antibiotic ointment (Terracortril) is placed in the lateral part of the external ear canal

Postoperative care

- The outer gauze dressing is removed after one week together with the Ivalon® ear wick
- Postoperative audiograms are done at 1-2 months, 1 year and 5 years

Reversal of stapedotomy

Fisch described *reversing the steps of the stapedotomy procedure* to reduce complications relating both to the incus (luxations

or subluxations) and footplate (subluxations / fractures / floating footplate). The point of departure for the following description of the surgery is exposure of the oval window as previously described.

- Check ossicular chain mobility and confirm stapes fixation
- Determine prosthesis length and trim the prosthesis accordingly
- Stapedotomy is performed
- Introduce the prosthesis and crimp it to the incus with the stapes arch still intact
- Cut the stapedius tendon and remove the arch of the stapes (*Figure 22*)
- Check the mobility of the ossicular chain with the prosthesis in place
- Seal the stapedotomy opening as previously described

Malleostapedotomy

This is a technique whereby both the incus and stapes are replaced by a single prosthesis in order to establish a direct connection between the malleus and the vestibule. It is indicated for stapes fixation with pathology of the incus and/or malleus head that rules out an incus-stapedotomy.

Figure 22: Stapedius tendon and posterior crus being cut with stapes prosthesis already in final position and crimped to incus

Surgical exposure

The *initial surgical steps* relating to end-aural approach, elevation of a tympanomeatal flap, and exposure are identical to that already described in this chapter for incus-stapedotomy. The point of departure of the description of the surgery that follows is exposure of the ossicular chain and oval window.

- Elevate the annulus, starting at the posterior tympanic spine
- The *chorda tympani* is left attached to the tympanic membrane
- The tympanic membrane is reflected until the anterior malleal process and ligament are exposed
- Assess the mobility of the malleus using a 1.5mm 45° hook
- Use a joint knife to separate the incudostapedial joint
- Mobility of the malleus and incus is reassessed
- Use a 2.5mm 45° hook to elevate *Shrapnell's membrane* from the proximal part of the handle of the malleus (just 1mm distal to the lateral malleal process) (*Figure 23*)

Figure 23: Elevating Shrapnell's membrane from proximal part of handle of malleus

- The final exposure for malleostapedotomy includes the pyramidal process,

oval window niche, tympanic segment of facial nerve, inferior part of the incudomalleolar joint and anterior malleal process and ligament (*Figure 24*)

Figure 24: Final view of middle ear structures before proceeding to remove incus

Removal of incus and malleal head

- Laterally rotate and mobilise the incus with a 1.5mm 45° hook, and remove it with crocodile forceps (*Figure 25*)

Figure 25: Removing incus with crocodile forceps

- If the incus is bulky then the long process of the incus is cut with a malleus nipper to avoid injury to *chorda tympani*

- If the ligament of the malleus is ossified, then a 0.8mm diamond burr is used to excise the neck and anterior process; separate the *chorda tympani* from the undersurface of the neck of malleus with a 2.5mm, 45° hook before drilling (*Figure 26*)

Figure 26: Diamond burr used to excise neck and anterior process of malleus so that malleus head may be removed

- The malleus head is then removed

Removal of arch of stapes

Crurotomy scissors are used to cut the anterior and posterior crura close to the footplate. Note in *Figure 27* that the anterior and posterior crura are equal length; in incus-stapedotomy the posterior crus would be shorter than the anterior crus

Figure 27: Anterior and posterior crura have been cut close to footplate

Preparation of prosthesis

- A 0.4mm diameter titanium piston with a total length of 8.5mm is used
- The distance between the stapes footplate and the lateral surface of the malleus handle (just below the lateral process) is measured with a malleable measuring rod; 0.5mm is added to this measurement
- Using the technique described for incus-stapedotomy the desired length is achieved by cutting the prosthesis on a special cutting block
- To confirm the correct length, the prosthesis is introduced into the middle ear with a large crocodile forceps, so that it extends between the malleus handle and stapes footplate (*Figure 28*)

Figure 28: Prosthesis placed in middle ear to check its length

- If the prosthesis extends above the malleus handle by 0.5mm, then the length is correct. A prosthesis that is too long may need to be cut shorter. If it is too short then it needs to be replaced
- To accommodate the slightly off-centre position of the malleus relative to the stapes footplate, the shaft of the piston must be adapted so that it lies perpendicular to the stapes footplate
- The loop of the prosthesis must be enlarged in order to fit over the malleus handle by stretching it open by moving

it along the shaft of a 1.5mm, 45° hook with a watchmaker's forceps

- The loop may need to be adapted so that it is oriented at 90° to the malleus handle

Performing the stapedotomy

- A perforation is made between the middle and inferior 1/3 of the footplate with a manual perforator or laser as for incus-stapedotomy (*Figure 29*)

Figure 29: Initial small stapedotomy

Introducing and crimping the prosthesis

- Accurate crimping is crucial to obtain good results; the larger exposure afforded by the approach described facilitates accurate crimping
- The prosthesis is picked up by its loop with a large alligator forceps at the required angle and placed on the footplate
- The loop of the prosthesis is placed over the malleus just distal to the lateral malleal process
- The loop is crimped to the malleus by applying the alligator forceps perpendicularly to the handle of the malleus. A *McGee Crimper/Wire Closure Forceps* may be helpful to deal with the angle between the stapedotomy and malleus
- If correctly crimped, the loop of the prosthesis should be perpendicular to

the inclination of the malleus handle and the shaft should be perpendicular to the stapes footplate (*Figure 30*)

Figure 30: The loop is perpendicular to malleus handle and shaft is perpendicular to footplate

Sealing the stapedotomy

The stapedotomy opening is sealed with connective tissue from the endaural incision and blood from the patient as described for incus stapedotomy.

Repositioning of tympanomeatal flap and wound closure: As for incus-stapedotomy

Postoperative care

- As for incus-stapedotomy
- Patients can fly after 2 weeks (as for incus-stapedotomy)
- Patients who have undergone malleostapedotomy are not permitted to scuba dive
