The surgical management of thyroglossal duct remnants (TGDRs) requires an understanding of the embryology of the thyroid gland, as failure to include the embryological course of the thyroid gland in the surgical resection increases the probability of recurrence.

Relevant Embryology

The thyroid gland originates in the base of the tongue at the foramen caecum. In early embryonic life the base of the tongue is adjacent to the pericardial sac. As the embryo unfolds, TGDRs may remain anywhere between the pericardial sac and the foramen caecum. A persistent thyroglossal duct courses through the base of the tongue from the foramen caecum. It then passes inferiorly, anterior to, and rarely through, the hyoid body, and often has a diverticulum that hooks below and behind the hyoid, before it courses towards a thyroglossal duct cyst or the thyroid gland (Figure 1).

The suprahypoid ductal segment may have a branching pattern like the tips of a broom (Figure 2). These multiple ductules communicate with secretory glands in the base of the tongue and might drain directly into the mouth.¹

Clinical presentation

TGDRs may present at any age as a cyst (Figure 3, 4), abscess, sinus, fistula or tumour, anywhere along the embryological course of the thyroid gland.

Figure 2: Schematic representation of the suprahypoid duct branching within the muscle of the base of tongue

Figure 3: Thyroglossal duct cyst in thyrohyoid region
Patients classically present with a mobile, painless mass in the midline of the neck in proximity of the hyoid. Occasionally the cyst may be off the midline (Figure 5).

Figure 6 illustrates the distribution of thyroglossal duct cysts.  

Figure 4: Thyroglossal duct cyst in thyrohyoid region

Figure 5: Thyroglossal duct cyst to left of midline overlying the lamina of the thyroid cartilage

Figure 6: Distribution of thyroglossal duct cysts

The cyst generally moves upward during deglutition or protrusion of the tongue because of its close anatomical relation to the hyoid bone. This is considered a reliable diagnostic sign, as it distinguishes it from other midline neck masses such as a lymph node and dermoid cyst (Figure 7).

Figure 7: Dermoid cyst

A lingual thyroid usually presents as a mass in the base of the tongue (Figures 8, 9), and this may be the patient’s only thyroid tissue in the majority of cases.
Preoperative evaluation

The principal issues to determine prior to surgery are:

*Is it a TGDR?* Unlike other midline masses, only TGDRs are treated with a Sistrunk operation. Therefore it is important to exclude other causes of midline masses prior to surgery such as dermoid cysts and lymph nodes.

*Is it the patient's only thyroid tissue?* Occasional a TGDR comprises the only functioning thyroid tissue, and its removal results in hypothyroidism. Ultrasound examination to establish the presence of normal thyroid tissue is a simple investigation. Should imaging not be possible, the surgeon should explore the neck to determine the presence of a normal thyroid gland.

*Is the patient hypothyroid?* The majority of patients with lingual thyroids are hypothyroid. Therefore patients with lingual thyroids should have a TSH level determined prior to surgery.

*Does the TGDR contain thyroid cancer?* Thyroid cancer occurs in only about 1% of operated TGDRs. A solid component and/or calcification on ultrasound examination should raise the possibility of carcinoma, most commonly papillary. However, even if the diagnosis of thyroid cancer is suspected it does not alter the type of surgery (Sistrunk operation).

**Surgical principles**

- It is imperative to achieve a complete resection of the TGDR and its embryonic tract so as to avoid symptomatic recurrence
- A thyroglossal cyst abscess should initially be aspirated and treated with antibiotics, not incised and drained, so as to facilitate complete resection once the infection has settled

**Sistrunk operation**

The Sistrunk operation is the standard of care for TGDRs. It includes resection of entire embryological tract i.e. the thyroglossal duct cyst, the central portion of the body of the hyoid bone, and a broad (≥1cm) core of suprahyoid muscle extending up to / close to the foramen caecum. The following description is for a cyst in the thyrohyoid region:

- An incision is made in a skin crease over the cyst. Note that that platysma
muscle may be absent in the midline, so take care not to puncture the cyst (Figure 10).

- Raise superior and inferior flaps in subplatysmal planes. The superior flap should be raised to approximately 2cms above the body of the hyoid.

- Identify the infrahyoid strap muscles that are stretched over the superficial aspect of the cyst (Figure 11).

Divide the cervical fascia vertically in the midline, separate the infrahyoid strap muscles, and expose the cyst (Figures 11, 12).

Figure 10: Initial skin crease incision

Figure 11: Expose the infrahyoid strap muscles overlying the cyst

Expose the body of the hyoid bone with diathermy (Figure 13).

Figure 12: Separate the infrahyoid strap muscles in the midline to expose the cyst

Figure 13: Exposed hyoid body

Divide the suprathyroid strap muscles (mylohyoid, geniohyoid) just above the hyoid body with diathermy, staying between the lesser cornua of the hyoid so as not to place the hypoglossal nerves or lingual arteries at risk of injury (Figure 14). Divide the inferior attachments of the thyroglossal duct cyst, and mobilise the deep aspect of the cyst from the thyrohyoid membrane up to the hyoid bone with sharp dissection.
Divide the hyoid bone about 1cm to each side of the midline with heavy scissors (children) or a bone cutter (Figure 15).

Figure 15: Mobilise the deep aspect of the cyst, and divide the hyoid bone

Next resect the suprathyroid thyroglossal duct. Do not attempt to visualise the thyroglossal duct, as branches of the duct may be transected in the process increasing the likelihood of recurrence. Using monopolar diathermy resect a 2cm wide core of tongue tissue (hyoglossus) in continuity with the remainder of the operative specimen, including the hyoid bone, directed at an angle of approximately 45° of the sagittal (vertical) plane towards the foramen caecum (Figure 16). If in doubt about the required direction, place a finger in the mouth and on the foramen caecum as a guide. It is remarkable how much base of tongue tissue can be resected without interfering with speech or swallowing. Note the proximity of the hyoid bone to the vallecula. Should the vallecula or base of tongue be accidentally entered, simply close the defect with vicryl sutures.

Figure 16: Superimposed image (yellow) illustrates direction of suprathyroid dissection and extent of final resection

The tongue defect is then partially obliterated with vicryl sutures (Figure 17). The two cut ends of the hyoid are not approximated, but left floating free. The supra- and infrahyoid muscles are approximated in a transverse plane, as is the platysma muscle, and the skin is closed over a drain. Antibiotics are not required unless the oral cavity has been entered.
Figure 17: Final defect in base of tongue up to just short of forman caecum with free floating cut ends of hyoid bone

**Recurrent TGDR**

Managing recurrent TGDR becomes challenging because cysts may be multifocal with the presence of fibrosis, distorted surgical landmarks and possible absence of hyoid bone. It is important to obtain an accurate description of the original surgery to determine whether the hyoid bone and suprahyoid tissues had been resected. An MRI scan should be done to serve as a roadmap for the surgeon to find residual TGDRs (Figure 18).
